Abstract

We present two patients with three-vessel disease and severely depressed left ventricular (LV) systolic function where viability analysis by cardiac magnetic resonance imaging demonstrated areas of near-transmural sub-endocardial fibrosis and hence little chance of regaining systolic function as judged by conventional analysis from radial function. Despite the pessimistic cardiac magnetic resonance imaging analysis, however, the patients underwent full revascularization and regained impressive increases in LV systolic function mainly based on improved longitudinal systolic segment function. The cases highlight that sub-epicardial, longitudinally oriented myocytes can contribute to overall LV systolic function and suggest taking their 'piston-function' into consideration when analysing viability.

Introduction

Cardiac magnetic resonance imaging (CMR) with late gadolinium enhancement (LGE) has become a preferred technique for determination of fibrosis and hence viability in ischaemic cardiomyopathy. Analysis is based on studies demonstrating improvement in radial contractility (myocardial thickening) following revascularization in hypo- or akinetic segments without substantial transmural fibrosis.^{1,2} With >75% transmural fibrosis, minimal improvement in radial contractility can be expected. However, analysis based on potential improvements in myocardial thickening mainly takes into account the function of mid-myocardial fibres and little account of the function of sub-epicardial fibres that (like the sub-endocardial) are involved in longitudinal function primarily.³ In patients with severe ischaemic cardiomyopathy, we extend viability analysis to

potential gains in not only radial but also in longitudinal left ventricular (LV) systolic function. As a demonstration of this way of thinking, we here present two patients with three-vessel coronary artery disease and severely depressed systolic function in whom revascularization was decided on despite >75% transmural fibrosis on LGE CMR because alternative options were considered too difficult.

Case reports

A 65-year-old woman presented with severe shortness of breath [New York Heart Association (NYHA) Class IV] and signs of a previous inferior wall infarction with pathologic Q-waves in II, III, and aVF on electrocardiogram. Coronary angiography proved severe three-vessel coronary artery disease, and following initial stabilization, the patient was initiated on guideline recommended heart failure medication. Four weeks

following initial admission, CMR showed a severely dilated LV [LV end-diastolic volume (LVEDV) of 265 mL (133 mL/m^2)], an LVEF of 14%, and widespread areas of near-transmural fibrosis in the left circumflex artery (LCX) and right coronary artery territories, but little fibrosis in the left anterior descending artery territory (*Figure 1A*; *Movies S1* and *S2*). Heart transplantation was decided against, and percutaneous coronary intervention (PCI) of all three vessels was performed

with a total of seven drug eluting stents. Three months after the PCI and on guideline recommended target dose of spironolactone, metoprolol, and maximum tolerated dose of losartan, a follow-up CMR showed that the LVEDV had decreased to 234 mL and LVEF improved to 37% (*Movies S3* and *S4*). The LGE imaging demonstrated no procedural infarction. Radial function improved very little, including the inferior and lateral wall with up to >75% fibrosis (*Figure 3*).

Figure 1 (A) Late gadolinium enhancement short axis images at a basal (upper left), midventricular (upper right), and apical (lower left) level and four-chamber image with widespread areas of near-transmural fibrosis in LCX and right coronary artery territories but little fibrosis in the left anterior descending artery territory. (B) Pre-percutaneous coronary intervention (PCI) two-chamber (upper panels) and four-chamber (lower panels) images with end-diastolic (left) and end-systolic (right) measurements of AV-plane displacement. (C) Post-PCI two-chamber (upper panels) and four-chamber (lower panels) images with end-diastolic (left) and end-systolic (right) measurements of AV-plane displacement, which improved to >9 mm in all segments.

However, atrioventricular (AV)-plane displacement improved from <3 to 9–11 mm in all segments, including the inferior wall where only a little sub-epicardial viable tissue was found (Figure 1B–C). Six months after her revascularization, the patient was symptom-free (NYHA Class I).

A 47-year-old previously healthy man presented with gradually increasing shortness of breath over the previous 3 months, on admission corresponding to NYHA Class IV. Initial work-up with electrocardiogram and troponins found

no acute coronary syndrome or pulmonary embolism but signs of a previous lateral myocardial infarction. Echocardiography showed severely depressed systolic function. The patient was put on maximum tolerated doses of guideline heart failure medication, including ramipril, carvedilol, and spironolactone. Six weeks following initial admission, CMR demonstrated a severely dilated LV [LVEDV of 336 mL (149 mL/m²)], an LVEF of 15% and 50% transmural fibrosis in the anterolateral wall at a basal and

Figure 2 (A). Late gadolinium enhancement short axis images at a basal (upper left), midventricular (upper right), and apical (lower left) level and four-chamber image with 50% transmural fibrosis in the anterolateral wall at a basal and midventricular level and up to 75% transmural fibrosis in the whole circumference at an apical level. (B) Pre-CABG two-chamber (upper panels) and four-chamber (lower panels) images with end-diastolic (left) and end-systolic (right) measurements of AV-plane displacement. (C) Post-CABG two-chamber (upper panels) and four-chamber (lower panels) images with end-diastolic (left) and end-systolic (right) measurements of AV-plane displacement, which improved from 1 mm in all areas to 6, 5, 5, and 7 mm in the two-plane (anterior and inferior) and four-plane (medial and lateral) views, respectively.

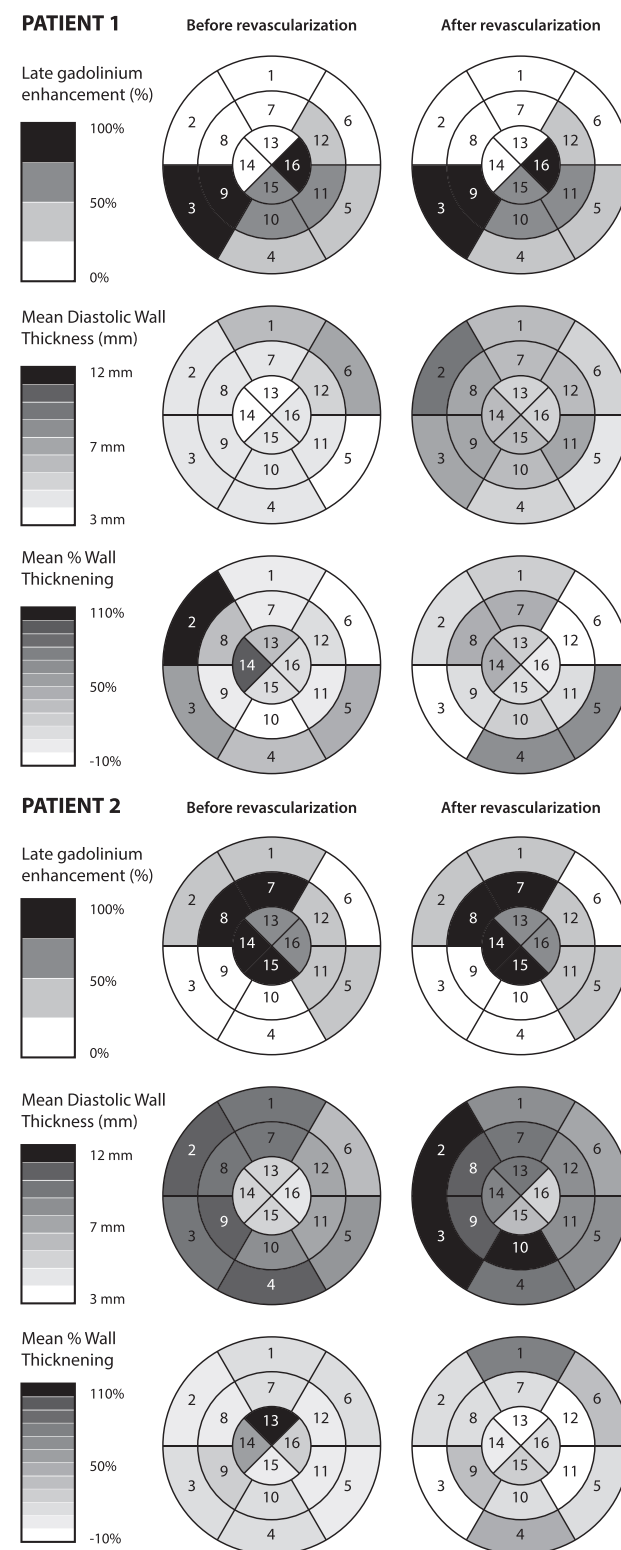

mid-ventricular level, and >75% transmural fibrosis in the whole circumference at an apical level (*Figure 2A*; *Movies S5 and S6*). Positron Emission Tomography (PET) imaging did not suggest significant viability, but based on LGE CMR, it was decided to pursue coronary artery bypass grafting (CABG) and following grafting of all territories, LV function improved. The patient recovered to NYHA Class I, the LVEDV decreased to 284 mL, and the LVEF improved to 28% (*Movies S7 and S8*). There was no additional LGE, documenting no CABG-related infarction. Radial function improved only slightly in the basal anterior wall (with approximately 50% fibrosis) and not at all in the mid-ventricular and apical segments with >75% fibrosis (*Figure 3*). Thus, the improvement of LV function was largely due to improvements in longitudinal motion. The AV-plane displacement improved from 1, 1, 1, and 1 mm to 6, 5, 5, and 7 mm in the two-plane (anterior and inferior) and four-plane (medial and lateral) views, respectively (*Figure 2B–C*). Longitudinal shortening of the mid-ventricular and apical part of the LV (with up to 75% transmural fibrosis) improved from 1, 0, and 0 mm to 11, 3 and 7 mm, respectively (determined corresponding to fixed anatomical points including insertion of papillary muscle and septal origin of the moderator band) (*Figure 2B–C*).

Discussion

Mid-myocardial fibres have a predominantly circumferential orientation, and hence, shortening of these fibres will mainly contribute to radial contractility. Sub-endocardial and sub-epicardial fibres have longitudinal orientations with the sub-endocardial describing a right-handed helix (as seen from the apex) and the sub-epicardial describing a left-handed.³ Based on this anatomical knowledge, it is understandable that >75% fibrosis will seriously limit radial contractility, whereas <25% fibrosis will not. If only the sub-epicardial layer is spared, substantial improvements in radial contractility cannot be expected with revascularization, but in our patients, revascularization of this viable sub-epicardial layer contributed to a significant improvement in longitudinal LV shortening. In these two cases, this improvement in longitudinal shortening helped improve overall systolic function as also reflected in ejection fractions. If findings from the STICH trial⁴ (median LVEF 28% and 27% in the medically treated group and CABG group, respectively) had been extrapolated to our patients, they may not have been revascularized. Although we cannot tell what would have happened to our patients if not revascularized but conservatively treated with heart failure medication, we believe that the impressive increases in LVEF with concomitant improvements in NYHA class from IV to I were probably largely due to the revascularization in itself. Beta-blocker therapy can contribute to an increase in LV function,^{5,6} but the effect of Angiotensin-converting enzyme

Figure 3 Segmental (American Heart Association 16-segment model) late gadolinium enhancement (%) (Rows 1 and 4); mean diastolic wall thickness (mm) (Rows 2 and 5); and mean wall thickening (%) (Rows 3 and 6) before (left panels) and after revascularization (right panels).

inhibitors and mineralocorticoid receptor antagonists on LVEF is less well established. Some echocardiographic studies have found a minor increase in LVEF with the latter,^{7,8} although not sufficient to explain the overall beneficial effect of treatment. These case reports may serve as an inspiration that in such patients, even in areas with only little sub-epicardial viable myocardium left, one should not completely dismiss such segments but consider applying analysis based on the kind of systolic function predominantly performed by these fibres, that is, the longitudinal shortening and hence 'piston-function' of the left ventricle. The cases may also serve as an inspiration for analysis with gadolinium analysis in future studies on revascularization in patients with ischaemic cardiomyopathy.
